Abstract

The medial axis is a classical representation of digital objects widely used in many applications. However, such a set of balls may not be optimal: subsets of the medial axis may exist without changing the reversibility of the input shape representation. In this article, we first prove that finding a minimum medial axis is an NP-hard problem for the Euclidean distance. Then, we compare two algorithms which compute an approximation of the minimum medial axis, one of them providing bounded approximation results.

Key words: Minimum Medial Axis, NP-completeness, bounded approximation algorithm.

1 Introduction

In binary images, the *Medial Axis* (MA) of a shape \mathcal{S} is a classic tool for shape analysis. It was first proposed by Blum [2] in the continuous plane; then it was defined by Pfaltz and Rosenfeld in [14] to be the set of centers of all maximal disks in \mathcal{S} , a disk being maximal in \mathcal{S} if it is not included in any other disk in \mathcal{S} . This definition allows the medial axis to be computed in a discrete framework, i.e., if the working space is the rectilinear grid \mathbb{Z}^n . The medial axis has the property of being a *reversible* coding: the union of the disks of $\text{MA}(\mathcal{S})$ is exactly \mathcal{S} .

¹ Supported in part by ANR grant BLAN06-1-138894 (projet OPTICOMB)

In order to compute the medial axis of a given discrete shape \mathcal{S} , we first proceed by computing the *Distance Transform* (DT) of \mathcal{S} . The distance transform is a bitmap image in which each point is labelled with the distance to the closest background point. For either d_4 or d_8 (the discrete counterparts of the l_1 and l_∞ norms), any given chamfer distance or the Euclidean distance d_E , the distance transform can be computed in linear time with respect to the number of grid points [18,4,7,11]. For the simple distances d_4 and d_8 , MA is extracted from DT by picking the local maxima in DT [18,4,16].

Polynomial time algorithms exist to extract MA from DT in the case of the chamfer norms or the Euclidean distance [16,17]. A Reduced Medial Axis (RMA) is presented in [8]: it is a reversible subset of the medial axis, that can be computed in linear time. Despite the fact that the medial axis exactly describes the shape \mathcal{S} , it may not be a set with minimum cardinality of balls covering \mathcal{S} : indeed, a maximal disk of the medial axis covered by a union of maximal disks is not necessary for the reconstruction of \mathcal{S} .

In this article, we investigate the minimum medial axis problem that aims at defining a set of maximal balls with minimum cardinality which cover \mathcal{S} . This problem has already been addressed with algorithms that experimentally filter the medial axis [5,15,6,13].

In section 2 we first detail some preliminaries and the fundamental definitions used in the remainder of the paper. Section 3 presents the proof that the minimum medial axis problem is NP-hard. Finally, we compare a greedy approximation algorithm with the approximation algorithm proposed in [15] (Section 4). The greedy approximation algorithm is a first bounded heuristic.

2 Preliminaries and Related Results

First of all, we recall definitions related to the discrete medial axis. Given a metric d , a (open) ball B of radius r and center p is the set of grid points q such that $d(p, q) < r$. In the following, we consider the Euclidean metric, while the extension of the results to other metrics (such as Chamfer norms for example) will be discussed in section 5.

Definition 1 (Maximal ball) *A ball B is maximal in a discrete shape $\mathcal{S} \subseteq \mathbb{Z}^n$ if $B \subseteq \mathcal{S}$ and if B is not entirely covered by another ball contained in \mathcal{S} .*

Based on this definition, the medial axis is given by:

Definition 2 (Medial axis) *The medial axis of a shape $\mathcal{S} \subseteq \mathbb{Z}^n$ is the set of all maximal balls in \mathcal{S} .*

Fig. 1. (*Left*) Unfilled points correspond to the centers of the medial axis balls for the Euclidean metric. In this figure, we represent the discrete maximal balls with the help of their continuous counterpart (open continuous balls) in order to make them distinguishable. (*Right*) A subset of the medial axis the balls of which still cover the entire shape.

45 In the remainder of the paper, we focus on dimension 2. By definition, the
 46 medial axis of a shape \mathcal{S} is a reversible encoding of \mathcal{S} . Indeed given the cen-
 47 ters and the radii associated to the medial axis balls, the input shape \mathcal{S} can
 48 be reconstructed entirely (this process is called the Reverse Distance Trans-
 49 formation [18,3,4,19,8]).

50 However, this representation is not minimum in the number of balls as illus-
 51 trated in Figure 1: the set of balls with highlighted centers in the left shape is
 52 the medial axis given by Definition 2. However, if we consider the subset of the
 53 medial axis depicted in the right figure, we still have a reversible description
 54 of the shape with fewer balls. In the following, we define the k -medial axis of
 55 a shape as follows:

56 **Definition 3 (k -Medial axis (k -MA))** *A k -medial axis of a shape $\mathcal{S} \subseteq$*
 57 *\mathbb{Z}^n is a subset of the medial axis of \mathcal{S} with k balls which entirely covers \mathcal{S} .*

58 In this paper, we address the problem of finding a subset of the medial axis
 59 that still covers all points of \mathcal{S} . In the remainder of the paper, we illustrate
 60 the proofs with discrete ball coverings of several complex discrete objects. In
 61 order to help the reader, we choose to represent each discrete ball with the
 62 polygon defined by the convex hull of the grid points inside this ball.

63 In computational geometry, covering a polygon with a minimum number of a
 64 specific shape (*e.g.* convex polygons, squares, rectangles, ...) usually leads to
 65 NP-complete or NP-hard problems [10]. From the literature, a related result
 66 proposed in [1] concerns the minimum decomposition of an orthogonal poly-
 67 gon into squares. At first sight, this result seems to be closely related to the
 68 k -MAP for the d_8 metric. However, in the discrete case, d_8 balls are centered
 69 on grid points and thus have odd widths. Due to this specificity, results of
 70 [1] cannot be used neither for the d_8 nor the Euclidean metrics. However, the
 71 proof given in the following sections is inspired by this related work.

72 3 NP-completeness of the k -Medial Axis Problem

73 **Definition 4 (k -Medial Axis Problem (k -MAP))** *Given a discrete shape*
 74 $\mathcal{S} \subseteq \mathbb{Z}^2$ *of finite cardinality and a positive integer k , does \mathcal{S} admit a k -MA ?*

75 In order to prove the NP-hardness of k -MAP, we use a polynomial reduction
 76 of the Planar-4 3-SAT problem. Let $\phi(V, C)$ be the boolean formula in Con-
 77 junctive Normal Form (CNF) consisting of a list C of clauses over a set V of
 78 variables. The *formula-graph* $G(\phi(V, C))$ of a CNF formula $\phi(V, C)$ is the bi-
 79 partite graph in which each vertex is either a variable $v \in V$ or a clause $c \in C$,
 80 and there is an edge between a variable $v \in V$ and a clause $c \in C$ if v occurs in
 81 c . A *Planar 3-SAT* formula ϕ is a CNF formula for which the formula-graph
 82 $G(\phi)$ is planar and each clause is a 3-clause (i.e., a clause having exactly 3
 83 literals).

84 In the following, we prefer a reduction based on the Planar-4 3-SAT problem:
 85 an instance of this problem is an instance of Planar 3-SAT such that the
 86 degree of each vertex associated to a variable in the formula-graph is bounded
 87 by 4. In other words, a variable may appear at most four times in the boolean
 88 formula.

89 **Definition 5 (Planar-4 3-SAT Problem)** *Given a Planar-4 3-SAT formula*
 90 $\phi(V, C)$, *does there exist a truth assignement of the variables in V which sat-*
 91 *isfies all the clauses in C ?*

92 Planar-4 3-SAT was shown to be NP-complete in [12].

93 The reduction from any given Planar-4 3-SAT formula ϕ to an instance of
 94 k -MAP consists in constructing a discrete shape $\mathcal{S}(\phi)$ and finding an integer
 95 $k(\phi)$ in polynomial time such that ϕ is satisfiable if and only if $\mathcal{S}(\phi)$ can be
 96 covered by $k(\phi)$ balls.

97 3.1 Variables

98 Let us first consider a geometrical interpretation of variables. Figure 2 presents
 99 a 4-connected discrete object, so called *variable gadget* in the following, defined
 100 by the set of grid points below the horizontal dashed line. The eight vertical
 101 parts of width 3 of the gadget (numbered on Figure 2) are called the *extremities*
 102 of the variable gadget. These extremities are used to plug the “wires” that
 103 represent the edges of a formula-graph.

104 Any minimum covering of this object has 72 balls. This comes first from the
 105 fact that all the balls depicted with a thick border belong to any minimum

106 covering; hence 40 balls are required. Moreover, on the remaining part, any two
 107 of the 32 circled points (on Figure 2) cannot be covered by a single ball, which
 108 proves that at least 72 balls are required to cover a variable gadget. Finally,
 109 coverings with exactly 72 balls can be exhibited (see Figure 2), which proves
 110 that a minimum covering has 72 balls. Then, if we consider the point p depicted
 111 in Figure 2, p can be covered by two different balls, which in turn implies
 112 two minimum different coverings. None of these minimum coverings allow
 113 protrusions from both one odd extremity and one even extremity. However,
 114 one minimum covering allows balls to protrude out at all odd extremities
 115 by one row of grid points (Figure 2 top); while another minimum covering
 116 allows balls to protrude out at all even extremities also by one row of grid
 117 points (Figure 2 bottom). These two coverings mimic the two possible truth
 118 assignments of a variable. Without loss of generality, the first covering will
 119 correspond to a True assignment, and the other one to a False assignment of
 120 the variable.

121 If the gadget represents the variable x , then each odd extremity carries the
 122 literal x , while each even extremity carries the literal \bar{x} . A protrusion from a
 123 variable extremity can be viewed as a signal 'True' sent from the variable to
 124 the clauses. Thus, wires which are used to connect variables and clauses are
 125 plugged on odd extremities for positive literals and on even extremities for
 126 negative literals.

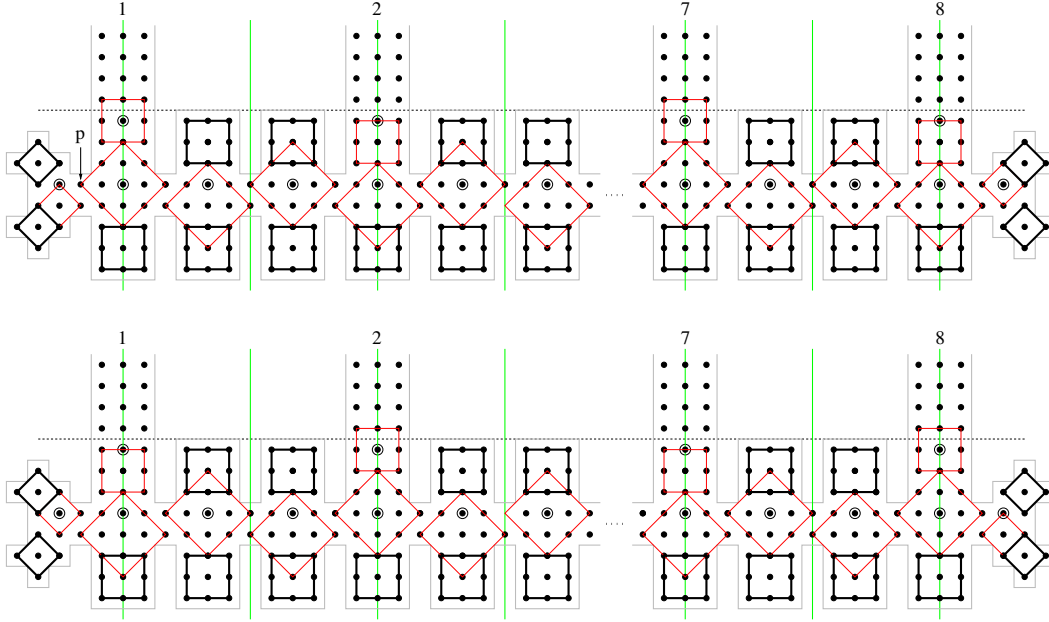

Fig. 2. Two minimum coverings of a variable gadget, corresponding to a True as-
 signement of the variable (top), and False assignment (bottom). Balls with a thick
 border belong to any minimum covering; any two circled points cannot be covered
 by a single ball.

127 Note that this object and its decomposition are invariant under rotation of

128 angle $\frac{\pi}{2}$. Furthermore, the extremities are centered on abscissas with equal
 129 values modulo 6 (represented by vertical lines of Figure 2). This property will
 130 be used to align the objects and to connect them to each other.

131 3.2 Wires

132 In order to connect variables to clauses, we need wires that correspond to edges
 133 in the embedding of the formula-graph. A wire must be designed such that it
 134 carries either a 'True' signal (protrusion), or a 'False' signal (no protrusion)
 135 from variable extremities to clauses without altering the signal (see Fig. 3).
 136 We can define a straight wire of width 3 and whose length is equivalent to
 137 $0 \bmod 3$, so that the signal sent at the left extremity of the wire will be
 138 propagated to the right extremity. Furthermore a wire can be bent at angle
 139 $\frac{\pi}{2}$ (see Fig. 3). In this case, two minimum decompositions still exist such that
 140 if a ball protrudes from one extremity of the wire, then another ball also
 141 protrudes out at the other extremity. Furthermore, straight wires and bends
 142 can be designed such that the alignment of the abscissa and ordinates of the
 143 shape is preserved (*i.e.* is constant modulo 3).

144 Now, if we consider a complex wire with straight parts and bends, the signals
 145 are propagated during the construction of the minimum covering from one
 146 extremity to the other one (by induction on the number of bends and straight
 147 parts).

Fig. 3. Wires carrying 'True' or 'False' signals - from left to right: a straight wire, a simple bend, a shift.

148 3.3 Clauses

149 Finally, we introduce the *clause gadget*, a component that geometrically sim-
 150 ulates a clause. This gadget is the set of grid points to the right of the vertical
 151 dashed line in Fig.4. Note that this gadget is not symmetrical because we shall
 152 not allow an open ball of radius $\sqrt{8}$ to be placed in its center.

153 Again, the 5 balls depicted with a thick border belong to any minimum cov-
 154 ering. Furthermore, any two of the 5 circled points (on Fig.4, left) cannot be
 155 covered by a single ball. Thus, independently covering this gadget requires at

156 least $5+5=10$ balls. However, if one open ball of radius 2 is protruding from
 157 some wire by one column, carrying a 'True' signal (e.g. the upper one in Fig.4,
 158 middle), then minimally covering the remainder of the gadget can be done
 159 with only 9 balls. Similarly, if two or three wires are carrying a protrusion, a
 160 minimum covering of the remainder of the clause gadget also has cardinality
 161 9. The case of three protrusions appears on the right in Fig.4, showing that
 162 even here 9 balls are still necessary to finish covering the gadget (similarly,
 163 any two of the 4 circled points cannot be covered by a single ball). Note that
 164 in general there may be several possible minimum coverings of the gadget,
 165 although only one is drawn here in each case.

166 According to these observations, it follows that the clause gadget can be min-
 167 imally covered by 10 balls if and only if no input protrusion is observed, in
 168 other words if and only if the corresponding clause is not satisfied. Otherwise,
 169 if at least one literal of the clause is set to 'True' (protrusion), implying that
 170 the clause is satisfied, then only 9 balls are necessary to cover the remainder
 171 of the gadget.

Fig. 4. Three minimum coverings of a clause gadget, depending on the following input signals (from left to right): False-False-False, True-False-False, True-True-True. Balls with a thick border belong to any minimum covering; any two circled points cannot be covered by a single ball.

172 3.4 Overall Construction and Proof

173 Given a Planar-4 3-SAT formula $\phi(V, C)$, we are now ready to construct $\mathcal{S}(\phi)$
 174 by drawing a variable gadget for each variable vertex in $G(\phi)$, a clause gadget
 175 for each clause vertex in $G(\phi)$, and drawing wires corresponding to the edges

176 in $G(\phi)$, thus linking each literal (the extremity of a variable gadget) to every
 177 clause where it occurs.

Fig. 5. Illustration of the transformation of a vertex of the planar orthogonal embedding into a variable gadget. In this case, the associated variable appears four times in ϕ , three times as a positive literal, and once as a negative literal.

178 **Lemma 1** *The shape $\mathcal{S}(\phi)$ can be computed in polynomial time in the size of*
 179 *ϕ .*

180 **PROOF.** We know from [20] that every planar graph with n vertices (with
 181 degree ≤ 4) can be embedded in a rectilinear grid in polynomial time and
 182 space. This algorithm produces an orthogonal drawing such that edges are
 183 intersection free 4-connected discrete curves. Since our variable gadgets and
 184 clause gadgets have a constant size and our wires have constant width, and
 185 since ϕ is an instance of Planar-4 3-SAT, it is clear that the construction of
 186 $\mathcal{S}(\phi)$ can also be done in polynomial time and space. For example, Figure 5
 187 illustrates how to bend the orthogonal drawing edges in order to connect them
 188 to our variable gadget extremities. \square

189 In the following, let $w(\phi)$ denote the minimum number of balls necessary to
 190 cover the wires of $\mathcal{S}(\phi)$, and let $k(\phi(V, C)) = 72 \cdot |V| + w(\phi) + 9 \cdot |C|$.

191 **Lemma 2** *If the formula ϕ is satisfiable, then there exists a covering of $\mathcal{S}(\phi)$*
 192 *with $k(\phi)$ maximal balls.*

193 **PROOF.** Given a truth assignment T of the variables V of ϕ such that
 194 ϕ is satisfiable, the following algorithm builds a covering of $\mathcal{S}(\phi)$ with $k(\phi)$
 195 maximal balls:

- 196 • cover the variable gadgets according to the truth assignment T ('True' or
 197 'False' value for each variable): each one requires 72 balls allowing protrusions
 198 in each extremity carrying a 'True' assignment (Section 3.1);

- 199 • cover the wires: since the grid embedding of $G(\phi)$ is computed in polynomial
200 time, so is $w(\phi)$; the protrusions from the extremities of the variables are
201 transmitted to the clause gadgets;
- 202 • cover the clause gadgets: since ϕ is satisfiable, at least one input wire of
203 each clause gadget carries a protrusion which implies that 9 maximal balls
204 are enough to cover each clause gadgets (Section 3.3).

205 Altogether, $72.|V| + w(\phi) + 9.|C| = k(\phi)$ maximal balls are used in this cov-
206 ering. \square

207 **Lemma 3** *If there exists a covering of $\mathcal{S}(\phi)$ with $k(\phi)$ maximal balls, then the*
208 *formula ϕ is satisfiable.*

209 **PROOF.** Suppose that there exists a covering of $\mathcal{S}(\phi)$ with $k(\phi)$ maximal
210 balls. By construction, $72.|V|$ plus $w(\phi)$ maximal balls are required to cover
211 the $|V|$ variable gadgets and the wires of $\mathcal{S}(\phi)$. This leaves us with $k(\phi) -$
212 $72.|V| - w(\phi) = 9.|C|$ maximal balls to cover the clause gadgets. Since there
213 are $|C|$ clause gadgets, each one is totally covered with 9 maximal balls in
214 the covering, which is possible only if at least one input wire of each clause
215 gadget carries a protrusion (Section 3.3). By construction, this means that the
216 clauses are all satisfied, and in turn that ϕ is satisfiable. \square

217 According to lemmas 2 and 3, there exists a truth assignement of the variables
218 in V which satisfies all the clauses in ϕ if and only if there exists a covering
219 of $\mathcal{S}(\phi)$ with cardinality $k(\phi) = 72.|V| + w(\phi) + 9.|C|$. Thus, if any instance
220 of the k -Medial Axis Problem could be solved in polynomial time, then we
221 would have a polynomial time algorithm to solve the Planar-4 3-SAT Problem.
222 Therefore, the k -MAP Problem is NP-hard. It is also clear that the k -MAP
223 problem is in NP, since we can easily verify in polynomial time wether a set of
224 k balls covers a discrete shape \mathcal{S} . Consequently, we have the following theorem:

225 **Theorem 4** *k -MAP is an NP-complete problem.*

226 As a consequence, finding a k -MA with minimum k of a shape \mathcal{S} is NP-hard.

227 4 Approximation Algorithms and Heuristics

228 Even if the theoretical problem is NP-hard, approximation algorithms can
229 be designed to find the k -MA with the smallest possible k . In the literature,
230 several authors have discussed simplification techniques to extract an approxi-
231 mation of the k -MA with minimum cardinality [5,15,6,13]. When dealing with

NP-hard problems, we usually want to have bounded heuristics in the sense that the results given by the approximation algorithm will always be at most at a given distance from the optimal solution.

In the following, we first detail the simplification algorithm proposed by Ragnemalm and Borgefors [15] and extended to 3-D by Borgefors and Nyström [6]. Then, we compare their result with a simple but bounded heuristic derived from the MINSETCOVER problem. These algorithms are presented in a generic way, for any dimension. The experiments are conducted in dimension 3, which is the highest standard dimension for digital objects. Even if the NP-completeness proof is established in dimension 2 in the previous sections, a similar result in dimension 3 can be conjectured.

4.1 Ragnemalm and Borgefors Simplification Algorithm

The algorithm is quite simple but provides interesting results: we first construct a covering map $CM(p) : \mathcal{S} \rightarrow \mathbb{Z}$ where we count for each discrete point $p \in \mathcal{S}$, the number of discrete maximal balls containing p . Basically, if a ball B contains a grid point p for which $CM(p) = 1$, then B is necessary to maintain the reconstruction and B belongs to any k -MA. Based on this idea, the approximation algorithm can be sketched as follows: let $\mathcal{F} = \text{MA}(\mathcal{S})$, we consider each ball B of \mathcal{F} by increasing radii. If for all points $p \in B$ we have $CM(p) > 1$, then we decide to remove B from \mathcal{F} and we decrease by one the value of $CM(p)$ for each $p \in B$. Then, we process the next ball.

The resulting set $\hat{\mathcal{F}}$ may be such that $|\hat{\mathcal{F}}| < |\mathcal{F}|$. In [15], the author illustrates the reduction rates with several shapes in dimension 2 but no simplification rate is formally given in the general case. In our experiments, instead of considering the medial axis of \mathcal{S} , we set $\mathcal{F} = \text{RMA}(\mathcal{S})$ [8].

If $\mathcal{F} = \{B_i, i = 1 \dots k\}$, the overall computational cost of this algorithm is $O(\sum_{i=1}^k |B_i| + k \log k)$.

4.2 Greedy Algorithm: a Bounded Heuristic

To have a bounded heuristic, let us consider another problem called the MINSETCOVER problem [9]: an instance $(\mathcal{S}, \mathcal{F})$ of the MINSETCOVER consists of a finite set \mathcal{S} and a family \mathcal{F} of subsets of \mathcal{S} , such that every element of \mathcal{S} belongs to at least one subset of \mathcal{F} . The problem is to find a family of subsets $\mathcal{F}^* \subseteq \mathcal{F}$ with minimum cardinality such that \mathcal{F}^* still covers \mathcal{S} . From the optimization MINSETCOVER problem, we can define the following decision problem: can we cover \mathcal{S} with a family \mathcal{F}^* such that $|\mathcal{F}^*| \leq k$ for a given

267 k ? This decision problem is known to be NP-complete [9]. Replacing \mathcal{S} by a
 268 discrete object and \mathcal{F} by the medial axis, we have a specific instance of the
 269 MINSETCOVER problem.

The greedy approximation algorithm is presented in 1. Even if this algorithm is simple, it provides a bounded approximation: if we denote $H(d) = \sum_{i=1}^d \frac{1}{i}$, $H_{\mathcal{F}} = H(\max |B|, B \in \mathcal{F})$ and \mathcal{F}^* the k -MA, the greedy algorithm produces a set $\hat{\mathcal{F}}$ such that:

$$|\hat{\mathcal{F}}| \leq H_{\mathcal{F}} \cdot |\mathcal{F}^*|$$

Algorithm 1: Greedy algorithm for MINSETCOVER.

Data: \mathcal{S} and \mathcal{F}

Result: the approximated solution $\hat{\mathcal{F}}$

$U = \mathcal{S};$

$\hat{\mathcal{F}} = \emptyset;$

while $U \neq \emptyset$ **do**

Select $B \in \mathcal{F}$ that maximizes $|B \cap U|;$
 $U = U - B;$
 $\hat{\mathcal{F}} = \hat{\mathcal{F}} \cup \{B\};$

return $\hat{\mathcal{F}}$

272 If we consider \mathcal{S} as a discrete object and \mathcal{F} the medial axis of \mathcal{S} , the medial
 273 axis simplification problem is a sub-problem of MINSETCOVER. Hence, Algo-
 274 rithm 1 provides a bounded heuristic for the medial axis reduction and this
 275 is, at the time of writing, the only known approximation algorithm for the
 276 minimum k -MA for which we have an approximation factor. Despite the fact
 277 that Algorithm 1 has a computational cost in $O(|\mathcal{S}||\mathcal{F}| \min(|\mathcal{S}|, |\mathcal{F}|))$, a linear
 278 in time algorithm can be designed, for instance in $O(\sum_{i=1}^k |B_i|)$ [9, Section
 279 37.3].

280 4.3 Experiments

281 In Figure 6, we present some experiments of both approximation algorithms.
 282 Two observations can be addressed: first, the reduction rate is very interest-
 283 ing since almost half of the medial axis balls can be removed. Secondly, the
 284 computational time of both algorithms are similar.

285 Despite the fact that Ragnemalm and Borgefors's algorithm gives slightly
 286 better results, the theoretical bound provided by the greedy algorithm makes
 287 this approach a bit more satisfactory.

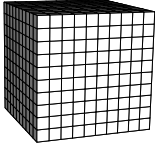

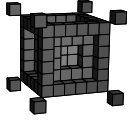

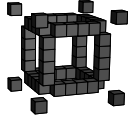

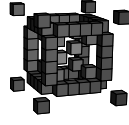

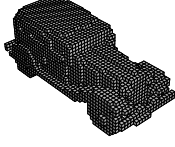

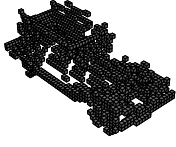

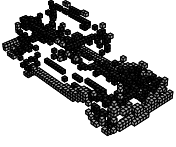

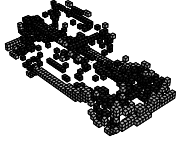

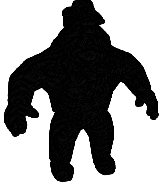

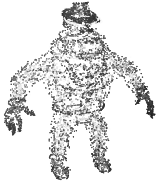

Objet	$\mathcal{F} = \text{MA}(\mathcal{S})$	$\hat{\mathcal{F}} \text{ RAGNEMALM ET AL.}$	$\hat{\mathcal{F}} \text{ Greedy}$
	 104	 56 (-46%) [$<0.01\text{s}$]	 66 (-36%) [$< 0.01\text{s}$]

	 17238	 6177 (-64%) [48.53s]	 6553 (-62%) [57.79s]

Fig. 6. Experimental analysis of simplification algorithms: *(from left to right)* Discrete 3-D objects, the discrete medial axis (ball centers), simplification obtained by [15] (ball centers), simplification obtained by the proposed greedy algorithm (ball centers). The cardinality of the sets are given below the figure with the reduction ratio (in percent) and the computational time.

5 Discussion and Conclusion

In this paper, we prove that finding a k -medial axis with minimum cardinality k of a discrete shape is an NP-hard problem. To do so, we provide a polynomial reduction from the Planar-4 3-SAT problem to the k -MAP. We also experimentally compare the greedy approximation algorithm which provides a bounded approximation, with existing simplification algorithms.

In the proof, we have considered the Euclidean distance based medial axis. In order to derive a proof for the other metrics, new gadgets must be defined. Some cases are trivial, such as the d_8 case for which only the variable gadget must be redefined (see Figure 7). Concerning other metrics, even if the gadgets may be difficult to design, we conjecture that theoretical results may be the same.

Future works concern both the complexity of specific restrictions of the

301 k -MAP, and the approximation algorithms. Concerning the theoretical part,
 302 the result we give induces the construction of very specific discrete shapes,
 303 whose genus depends on the number of cycles in the Planar-4 3-SAT instance.
 304 Thus, an important question is whether k -MA is still NP-complete in the
 305 case of connected discrete shapes without holes. Concerning approximation
 306 algorithms, experiments show that the results of the greedy approximation
 307 algorithm are slightly worse than other existing algorithms. An important fu-
 308 ture work is to merge the two approaches to improve the results while keeping
 309 the bounded approximation.
